Abstract: Nanostructured metal oxide semiconductors have shown outstanding performances in photoelectrochemical (PEC) water splitting, but limitations in light harvesting and charge collection have necessitated further advances in photoelectrode design. Herein, we propose anodized Fe foams (AFFs) with multidimensional nano/micro-architectures as a highly efficient photoelectrode for PEC water splitting. Fe foams fabricated by freeze-casting and sintering were electrochemically anodized and directly used as photoanodes. We verified the superiority of our design concept by achieving an unprecedented photocurrent density in PEC water splitting over 5 mA cm\(^{-2}\) before the dark current onset, which originated from the large surface area and low electrical resistance of the AFFs. A photocurrent of over 6.8 mA cm\(^{-2}\) and an accordingly high incident photon-to-current efficiency of over 50% at 400 nm were achieved with incorporation of Co oxygen evolution catalysts. In addition, research opportunities for further advances by structural and compositional modifications are discussed, which can resolve the low fill factor behavior and improve the overall performance.

Owing to the rapidly increasing demands on sustainable hydrogen production, intensive efforts have been devoted for the utilizations of solar energy for water electrolysis.[4-9] For efficient solar water splitting, development of photocatalysts or combinations of photovoltaic and water electrolyzer has been performed and significant advances have been achieved.[14-19] Additionally, water photoelectrolysis based on photoelectrochemical (PEC) water splitting is receiving much attention owing to its superior characteristics such as feasible solar-to-hydrogen conversion in a single device that enables direct collection of H\(_2\) without separation from evolved oxygen in industrially optimized systems.[20-22]

For the PEC water splitting, there have been numerous reports on the design and preparation of nanostructured metal oxide semiconductor photoelectrodes. Since the pioneering work employing titania,[23] various metal oxides, such as TiO\(_2\),[24-31] WO\(_3\),[32-34] CuO,[35,36] CuO\(_2\),[37-39] BiVO\(_4\),[40-42] and α-Fe\(_2\)O\(_3\),[43-51] have been frequently used as photoelectrodes. Among these, α-Fe\(_2\)O\(_3\) is considered to be one of the most attractive oxides for water photoelectrolysis, because it is chemically stable, environmentally favorable, and earth-abundant. A number of nanostructures with appropriate dopants were proposed to enhance the performance but there are still plenty of opportunities for further advances.[52-54]

Herein, we propose anodized Fe foam (AFF) as a new type of photoelectrodes and investigate its application for PEC water splitting. We designed the photoanodes to have the following ideal characteristics: 1) large surface area for light harvesting, 2) low-dimensionally confined semiconductor structure for enhanced charge transport, and 3) three-dimensionally extended current collector with very low resistance. By anodic oxidation of Fe foams, which were prepared by freeze-casting,[55,56] vertically aligned iron oxide nanoflakes were synthesized on the Fe foam surfaces. AFFs in PEC water splitting generated large photocurrents, verifying the general advantages of this design concept.

AFF photoelectrodes were prepared by electrochemical anodic oxidation of freeze-cast Fe foam (Figure 1a), for which a modified procedure of the method in previous reports was

potential ($J-V$) curve as shown in Figure 3b. The most notable characteristic of the AFF photoanode was the large photocurrent density. The onset of electrochemical water oxidation of hematite in dark condition is known to be around 1.55 V vs. reversible hydrogen electrode (RHE)\textsuperscript{[27]} and we observed a photocurrent density exceeding 5 mA cm\textsuperscript{-2} before reaching the dark current onset (5.49 ± 0.34 mA cm\textsuperscript{-2} at 1.55 V); this is the highest value yet reported for PEC water splitting employing an iron oxide photoelectrode. This superb performance obtained from the AFF photoanode in water photoelectrolysis can be attributed to the large surface area for light harvesting, two-dimensionally confined semiconductor structure for enhanced charge transport, and threedimensionally extended current collector with a very low sheet resistance, which was measured to be only 2.4 m$\Omega$ square$^{-1}$. The photocurrent density at 1.23 V vs. RHE calculated from the incident photon-to-current efficiency (IPCE) was 2.30 mA cm$^{-2}$, which corresponds to that obtained from the $J-V$ curve (2.29 mA cm$^{-2}$). The photocurrent onset was around 0.79 V vs. RHE as calculated from the averaged result displayed in Figure S5; this is consistent with a previous report wherein anodized Fe foil was used as the photoanode.\textsuperscript{[28]}

In the previous studies of PEC water splitting based on hematite photoelectrodes, a steep increase in current was observed after the photocurrent onset. Subsequently, the current reaches a limiting value that is governed by the light harvesting and charge collection properties of the photoelectrode.\textsuperscript{[32,33]} In contrast, in water photoelectrolysis using an AFF, the $J-V$ curve shows a relatively gentle photocurrent slope after the onset potential (similar to low fill factoring behavior in photovoltaic), and this can be understood as the consequence of severe charge recombinations occurring in the inner part of the nanostructured oxides. The diffusion length of holes in hematite is well known to be around 2–4 nm,\textsuperscript{[29, 32]} and thus nanostructure thinner than 8 nm are required for near-complete utilization of photo-generated charge carriers. The thicknesses of nanoflakes and porous nano-oxides beneath the two-dimensional structures exceeded 8 nm and the holes generated in the innermost region of the nanostructured iron oxide were not able to participate in water photooxidation because of recombination with electrons. Our results are in line with previous work by Mohaptra et al. wherein iron oxide nanotubes with wall thicknesses of around 5–20 nm manifested $J-V$ curves with low fill factoring behav-

Inset shows the IPCE data. c) Quantification of gas evolution under AM 1.5G illumination at 1.23 V vs. RHE. The inset shows the photocurrent density during the water splitting reaction and the dashed lines display the amount of gases at 100% Faradaic efficiency.
ior and no indication of limiting photocurrent prior to the dark current onset. Additionally, as can be seen from the transmittance spectrum in Figure S6, the 500 μm thick AFF was completely opaque, suggesting that the rear part of AFF cannot participate in harvesting of photons for water splitting. Therefore, a significant amount of charge recombination at electrode/electrolyte interface takes place in the rear-most region, resulting in the drop of overall performance. However, this also implies that there are possibilities for achieving enhanced performance by optimizing the photoelectrode thickness.

The Faradaic efficiency of the AFF was obtained under AM 1.5G illumination by gas chromatography (GC) analysis. Figure 3c shows the amount of evolved H₂ and O₂ gases at 1.23 V vs. RHE and the corresponding current densities are displayed in the inset. The Faradaic efficiency during 8 h of operation was over 80% (80.1% by H₂ and 88.6% by O₂). Interestingly, photocurrent density increased as the reaction time exceeds 3 h and the evolution rate of H₂ and O₂ gases also increased. The photocurrent surpassed the initial value after 6 h, with Faradaic efficiency being close to unity (97.3%). In order to address this phenomenon, investigations on chemical transition of the photoelectrode were performed. According to the XRD patterns and corresponding Rietveld refinement results of the AFFs before and after the reaction (Figure 4a and Table S2), inactive magnetite was transformed into the active hematite phase with the atomic ratio of hematite/magnetite changed from 1.97 to 2.19. This can be ascribed to an Fe³⁺/Fe²⁺ transition caused by holes generated from photon absorption. Moreover, changes in chemical states of the AFFs’ surface were also characterized by XPS analyses. In the Fe 2p XPS spectra displayed in Figure S7, the 2pₓ₂₃ peak of the bare AFF is located at 710.8 eV and the distance between the 2pₓ₀ and 2pₓ₂ peaks is 13.6 eV, indicating that the surface of AFF is mainly hematite. However, the 2p peaks slightly shift to a lower binding energy after the reaction, attributed to the formation of iron oxyhydroxide (FeOOH) on the surface in the basic media. FeOOH is a well-known oxygen evolution catalyst (OEC), and the FeOOH layer seems to have contributed to the increment of the photocurrent density. Despite these chemical transitions, the morphology of AFFs was maintained after 8 h of water splitting (Figure 4b–e), and this can be attributed to the extremely small thickness (below 1 nm) of the FeOOH layer observable from the TEM images in Figure S8.

For further enhancement in performance, we decorated the surface of AFF with Co OECs by electrodeposition, as schematically illustrated in Figure 5a. Uniform deposition of Co OECs was confirmed by SEM (Figure 5b–e) and TEM analyses (Figure 5f), wherein deposited nanoparticles with lattice spacing of Co (101) are clearly visible, and also by obtaining elemental EDS maps (Figure 5g–i) of the region shown in Figure 5f. Figure 5j displays the performance of PEC water splitting based on the Co-decorated AFF photoanode. Compared to the case of bare AFF, the photocurrent onset was reduced by 0.19 V (an onset of 0.61 was obtained from the averaged results displayed in Figure S9), and the photocurrent density at 1.23 V vs. RHE exceeded 3 mA cm⁻² with an IPCE value at 400 nm of over 50%. The integrated

photocurrent density based on the IPCE spectra was 3.06 mA cm$^{-2}$, a reasonable value considering the 3.25 mA cm$^{-2}$ obtained from the J–V result. Also, the photocurrent density reached 6.8 mA cm$^{-2}$ before the dark current onset (6.82 ± 0.53 mA cm$^{-2}$ at 1.55 V); this is the highest value ever reported, to the best of our knowledge, in the case of iron oxide.

In summary, we have constructed an anodized Fe foam photoelectrode for PEC water splitting and verified its superior performance by obtaining photocurrent density exceeding 5 mA cm$^{-2}$ (6.8 mA cm$^{-2}$ with Co catalysts) prior to the onset of water electrolysis. The anodized Fe foam is promising because it has ideal characteristics such as a large surface area, low-dimensionally confined semiconductor nanostructure, and three-dimensional metal foam current collector with a very low electrical resistance. Moreover, there is room for further optimization in terms of additional structural/compositional modification and device architecture. These combinatory advantages present in AFF-based PEC water splitting and viability for further extension of this design concept to other materials are anticipated to bring advances to the current technology of PEC H$_2$ production and to the general strategies for utilization of solar energy in various photocatalyses that are thermodynamically uphill.
